Abstract

Introduction: Because of the high frequency of intrauterine growth restriction, foetal distress, and preterm, women with pre-eclampsia have a higher rate of caesarean delivery. Cesarean section, on the other hand, increases the risk of pre-eclampsia-related cardiac morbidity. This is attributed to pre-eclampsia patients' altered hemodynamics. Both spinal and general anaesthesia come with this risk. This highlights the necessity for research comparing the outcomes of Cesarean sections performed under subarachnoid block to general anaesthesia, since this will aid clinicians in underdeveloped countries in making decisions.

Objective: To compare the outcome of spinal anesthesia and general anesthesia inCesareandelivery forwomen with severe pre-eclampsia.

Methods: A retrospective study of women with severe pre-eclampsia requiring Cesarean section was carried out in our hospital. A total of 48 patients were enrolled in the study. Maternal age, parity,gestational age at delivery, booking status, Apgar scores, maternal and perinatal mortality of the sub-arachnoidblock groupwere compared with those of general anesthesia groupusing Studentt-test.

Results: There were no significant difference between the two groups in overall maternal mortality (5%vs.7%, P=0.5) and perinatal mortality (2.7% vs. 11.9%, P=0.15). The general anesthesia group had significantlymorebirthasphyxiathan the spinalgroup (56%vs. 27%, P=0.0006).

Conclusion: There was statistically significant difference in the perinatal mortality outcome of cesarean delivery between women with severe pre-eclampsia who had regional anesthesia and those that had general anesthesia. Mean maternal age was statistically significant. There was significantly higher proportion of birth as physiain babies of women who received general anesthesia. P value<0.05 with respect to post operative convulsions & acute renal failure which is statistically significant.

Introduction

Because of the high frequency of intrauterine growth restriction, foetal distress, and preterm, women with pre-eclampsia have a higher rate of caesarean delivery. Cesarean section, on the other hand, increases the risk of pre-eclampsia-related cardiac morbidity¹. This is attributed to pre-eclampsia patients' altered hemodynamics. Both spinal and general anaesthesia come with this risk^{2,3}. This highlights the necessity for research comparing the outcomes of Cesarean sections performed under subarachnoid block to general anaesthesia, since this will aid clinicians in underdeveloped countries in making decisions.

Recently, spinal anesthesia (SA) has been recognized to have a place in operative management in pre-eclampsia parturients because it is more practical, has faster onset and with fewer complications^{3,4}. There is alsoevidence that its use in pre-eclampsia is increasing. A concern has been raised that SA might be unsuitable forpre-eclamptic patients as there is a potential for profound hypotension that could further compromise an alreadypotentially compromisednewborn andworsen neonatal outcome. On the otherhand, there are reports statingthat patients with severe pre-eclampsia experience less hypotension during SA than healthy parturients. Minimalhemodynamic effects from spinal anesthesia in healthy pregnancy have been demonstrated when using a lowdose of bupivacaine (under 10 mg bupivacaine) but this has not been sufficiently investigated in pre-eclamptictoxemia^{5,6}. Pre-eclampsia has an incidence of around 8% of pregnancies and is a major cause of maternalmorbidityandmortality.

Methodology

• Severepre-eclampsia: Systolic blood pressure ≥ 160 mm Hg and/or diastolic blood pressure ≥ 110 mm Hg with $\geq 2+$ of Protein uria on dipstix urin alysis.

• Booked: women who received an tenatal care at the study center.

Sub-arachnoid block is usually done with 0.5% bupivacaine. For general anesthesia, rapid sequence induction with Sellick's maneuver and a relaxant technique are used. Sodium thiopentone 4-6 mg/kg and suxamethonium1-2 mg/kg are used for induction and endotracheal intubation. Anesthesia is maintained with pancuronium, halothane and oxygen/nitrousoxide.

The records of all women who had Cesarean section for severe pre-eclampsia were retrieved. Data on maternal age, parity, gestational ageat delivery, booking status, A pgarscores, maternal mortality and perinatal mortality were extracted.

The subjects were classified into two categories: Group A was patients that had spinal anaesthesia while group B comprised of patients that had general anesthesia.

The background characteristics and outcomes were compared between the two groups using χ^2 , Student t-test, using SPSS version 23.0 statistical software. Differences were considered significant if *P*<0.05.

Exclusioncriteria

- mildpre-eclampsia
- Medicaldisordersinpregnancy,
- multiplepregnancies,
- gestationalagelessthan32weeks,
- Eclampsia

Discussion

It is postulated that the main cause of development of preeclampsia is a functional imbalancebetween the endogenous vasodilators (prostacyclins PG I2) and vasoconstrictors (thromboxane A2) leading to arteriolar vasospasm and hypoperfusion of vital organs. Anesthesia for C section can worsen the maternal circulation further and can influence the outcome of the new born7.

Severepre-eclampsiaisdefinedasanyoneofthefollowingoccurringafterthe20th week of pregnancy: (i) severe hypertension (systolic blood pressure >160mm Hgordiastolic blood pressure > 110 mm Hg);

(ii) protein uria >5 g per 24 h;

(iii) olig uria < 400 ml per 24 h;

(iv) cerebral irritability or visual disturbances;

(v) epigastricor right upper quadrant pain (liver capsule distension); or (vi) pulmonary edema 8. The reareseveral reasons for preferring spinal anaesthesia to general anaesthesia for caesarean section. Babies born to mothers having spinal anaesthesia may be more alert and lesssed at edas they have not received any general anaesthetic agents through the placental circulation. As the mother's airway is not compromised, there is a reduced risk of aspiration of gastric contents causing chemical pneumonitis. Although spinal anaesthesia is not contraindicated in the presence of mild preeclampsia, such patients may have altered clotting function and are relatively hypovolaemic. There is always a chance that a pre eclampticpatient may suddenly havea convulsion and anticonvulsant drugs (midazolamorthiopentone sodium) must be immediately available. The advantages and disadvantages of spinal versus general anaesthesia will have to be carefully considered for each patient 7,8. There was no statistically significant difference with regards to demographic profile of patient except for mean maternal age. Exclusion criteria helped to remove the confounding factor retaining the accuracy of the study. Significantly more babies with Apgarscores less than 7 at 1 and 5 minutes were recorded in the general anesthesia group than in the sub-arachnoid block group. However, the perinatal mortality was not significantly different between both groups. The proportion of maternal deaths from anesthetic complications was not significantly different between both groups supported by Wallace et al1. In the study of Ahmed et al.11, theeffects of spinal anesthesia was compared with general anesthesia in preeclamptic parturients. Hypotension wasseen in 47.1% of spinal group and 68.8% of general group became hypertensive. Antoine et al. (2003)12 showedthat patients with severe preeclampsia experience less hypotension (6 times lesser) during spinal anesthesia with 0.5% Bupivacaine. One study (Shifman and Filippovich, 2003)13 contains data on retrospective observationstudy of 54 cases with subarachnoid anesthetic management for cesarean

section in preeclampsia. The resultsshowed that no complications were detected in mothers and fetuses of the experimental group and confirmed thesafety of this method in patients with preeclampsia. In the study of Ahmed et al.11, Also, the incidence andseverity of postoperative complications (hypertension, pulmonary edema, delayed awaking and mortality) werehigher in general group in compared with spinal group.Furthermore, because of its simplicity and rapidity wealso believe that spinal anesthesia should be considered as an alternative to general anesthesia for emergency cesarean delivery in preeclamptic women who have been adequately prepared with judicious amount of IVpreload.

The absence of studies from this environment demonstrating advantage of sub-arachnoid block overgeneral anesthesia for severe pre-eclamptics may be a contributory factor to the preponderance of general anesthesia noted in this study.

Conclusion

Both the techniques of general as well as spinal anaesthesia, can be used for severe Preeclampticpatients for caesarean delivery. Haemodynamic changes in both techniques are acceptable and manageable during the operation, but post operative morbidity, requiring admission in ICU and mortality, are more common after general anaesthesia. Stay in the hospital is also prolonged in these patients as compared to patients operated under spinal anaesthesia. It is therefore concluded that spinal anaesthesia could be considered as first choice for severe preeclamptic patients, which is as safe as general anaesthesia, with less postoperative morbidity and mortality

The findings in this study support the previous studies which showed significant difference in perinatalmortality & birth asphyxia in outcome of Cesarean delivery between women with severe pre-eclampsia who had spinal and those that had general anesthesia. However, there was significantly higher proportion of birth as phyxiain womenwho received general anesthesia.
